

Demand for differentiated products

TSE, MRes

Outline

Theory and estimation with aggregate data

To go further:

- What to do with micro data?
- With a combination of aggregate and micro data

Demand for differentiated products

Products are differentiated

Very few exception: commodities (oil, gold, materials, cement...)

Consequence: demand for a product depends on prices of the competing products

Understanding demand for a product includes understanding substitution across products:

- Own price elasticity
- Cross price elasticities

Why do we want to estimate demand?

Understanding demand is crucial for firms (marketing and pricing departments)

From demand and prices, we can infer margins, mark up which indicate firms' market power (see Lecture 2)

Understanding product demand is crucial for sectoral policies (e.g carbon tax)

Outline

- 1 Theory and estimation with aggregate data
- 2 Estimation with micro data
- 3 Appendix: GMM estimation

Reduced form and curse of dimensionality

One could think about estimating:

$$\begin{aligned}\ln Q_1 &= \alpha_0^1 + \alpha_1^1 \ln p_1 + \alpha_2^1 \ln p_2 + \cdots + \alpha_N^1 \ln p_N + \epsilon_1 \\ \ln Q_2 &= \alpha_0^2 + \alpha_1^2 \ln p_1 + \alpha_2^2 \ln p_2 + \cdots + \alpha_N^2 \ln p_N + \epsilon_2 \\ &\vdots \\ \ln Q_N &= \alpha_0^N + \alpha_1^N \ln p_1 + \alpha_2^N \ln p_2 + \cdots + \alpha_N^N \ln p_N + \epsilon_N\end{aligned}$$

Problem = curse of dimensionality: $(N + 1)^2$ parameters to estimate

Model not micro-founded

Presentation of the BLP model

Berry, Levinsohn & Pakes (1995), and Berry (1994)

Model to estimate demand with aggregate data, i.e. total quantity purchased at the product level

With product-level aggregate data, the BLP model is able to:

- Include product differentiation through observed and unobserved product characteristics
- Control for price endogeneity
- Include unobserved individual heterogeneity in preferences

Very influential model, used a lot by researchers and practitioners (competition authorities)

Remark: BLP also develop a supply model, see next lecture.

Overview of the model

Discrete choice model, choice of one product among the set of products available

One option is not to purchase (outside option), typically denoted by 0

Model is micro-founded: starts from specification of utility, as a function of characteristics of products (including price)

Individuals do not have preference for products but for product characteristics

Advantage = move from product space to characteristics space (smaller!)

Each consumer chooses the option associated to the highest utility

Basic idea: aggregate sales represent the aggregation of individual optimal choices

Objective = estimate parameters of utility from aggregate sales data

The BLP model

$$U_{ik} = \mathbf{x}'_k \boldsymbol{\beta}_i - \alpha_i p_k + \xi_k + \varepsilon_{ik}$$

- \mathbf{x}'_k : vector of observed product characteristics
- p_k : price of the product, endogenous: $\mathbb{E}(\xi|\mathbf{p}) \neq 0$
- ξ_k : unobserved product characteristics (unobserved to the econometrician, but known by individuals and firms)
- α_i price sensitivity
- $\boldsymbol{\beta}_i$ vector of preference for product characteristics
- ε_{ik} : individual and product taste shock, iid across individuals and products

Important assumption: ξ_k are the same for all consumers, no unobserved heterogeneity in the valuation of the unobserved characteristics (see Berry & Haile, 2014)

The BLP model

We typically assume α_i, β_i are drawn from known distributions. And we want to estimate the parameters of the distributions. We can usually decompose the individual parameters into a mean and an individual deviation:

$$\begin{aligned}\alpha_i &= \bar{\alpha} + \sigma^p \zeta_i^p \\ \beta_i^l &= \bar{\beta}^l + \sigma^l \zeta_i^l\end{aligned}$$

rk: l index for the characteristics.

$\bar{\alpha}$ and $\bar{\beta}^l$ are the mean parameters and σ^p and σ^l are the standard deviations. ζ_i^p and ζ_i^l are draws from a known distribution.

We can rewrite the utility function as:

$$U_{ik} = \delta_k + \mu_{ik} + \varepsilon_{ik}$$

- δ_k : mean product utility common to everyone:

$$\delta_k = \sum_l x_k^l \bar{\beta}^l - \bar{\alpha} p_k + \xi_k$$

- μ_{ik} : individual-specific deviation from the mean utility

$$\mu_{ik} = \sum_l x_k^l \sigma^l \zeta_i^l - p_k \sigma^p \zeta_i^p$$

The logit model

The error terms ε_{ik} are assumed to be extreme value distributed across individuals and products

Cumulative distribution function:

$$F_{\varepsilon}(x) = \exp[-\exp(-x)]$$

Probability density function:

$$f_{\varepsilon}(x) = \exp(-x) \exp[-\exp(-x)]$$

The probability that consumer i chooses product j has a closed-form solution:

$$P_{ij} = \frac{\exp(\delta_j + \mu_{ij})}{\sum_{k=0}^J \exp(\delta_k + \mu_{ik})}$$

Derived from utility maximization when ε_{ik} are iid extreme value distributed

Proof in a simple case

Proof with 3 products: $J = 3$, assume $\mu_{ik} = 0$

$$\begin{aligned}
 & \Pr(\text{choice} = 2) \\
 = & \Pr(U_2 > U_1 \text{ and } U_2 > U_3) \\
 = & \Pr(\varepsilon_1 < \varepsilon_2 + \delta_2 - \delta_1 \text{ and } \varepsilon_3 < \varepsilon_2 + \delta_2 - \delta_3) \\
 = & \int_{-\infty}^{+\infty} f_{\varepsilon}(x) \Pr(\varepsilon_1 < \varepsilon_2 + \delta_2 - \delta_1 \text{ and } \varepsilon_3 < \varepsilon_2 + \delta_2 - \delta_3 | \varepsilon_2 = x) dx \\
 = & \int_{-\infty}^{\infty} f_{\varepsilon}(x) \left[\int_{-\infty}^{x+\delta_2-\delta_1} f(\varepsilon_1) d\varepsilon_1 \cdot \int_{-\infty}^{x+\delta_2-\delta_3} f(\varepsilon_3) d\varepsilon_3 \right] dx \\
 = & \int_{-\infty}^{\infty} \exp(-x) \exp[-\exp(-x)] \cdot F_{\varepsilon}(x + \delta_2 - \delta_1) \cdot F_{\varepsilon}(x + \delta_2 - \delta_3) dx \\
 = & \int_{-\infty}^{\infty} \exp(-x) \exp[-\exp(-x)] \cdot \exp[-\exp(-x - \delta_2 + \delta_1)] \\
 & \cdot \exp[-\exp(-x - \delta_2 + \delta_3)] dx
 \end{aligned}$$

Proof in a simple case

Proof cont'd

$$= \int_{-\infty}^{\infty} \exp(-x) \exp \left(-\exp(-x) \cdot [1 + \exp(\delta_1 - \delta_2) + \exp(\delta_3 - \delta_2)] \right) dx$$

Change of variable: $t = \exp(-x)$, $dt = -\exp(-x)dx$

$$\begin{aligned} &= \int_{+\infty}^0 -dt \exp \left(-t [1 + \exp(\delta_1 - \delta_2) + \exp(\delta_3 - \delta_2)] \right) \\ &= \int_0^{+\infty} \exp \left(-t [1 + \exp(\delta_1 - \delta_2) + \exp(\delta_3 - \delta_2)] \right) dt \\ &= \left[\frac{\exp \left(-t [1 + \exp(\delta_1 - \delta_2) + \exp(\delta_3 - \delta_2)] \right)}{-(1 + \exp(\delta_1 - \delta_2) + \exp(\delta_3 - \delta_2))} \right]_0^{+\infty} \\ &= 0 - \frac{1}{-(1 + \exp(\delta_1 - \delta_2) + \exp(\delta_3 - \delta_2))} \\ &= \frac{\exp(\delta_2)}{\exp(\delta_1) + \exp(\delta_2) + \exp(\delta_3)} \end{aligned}$$

The simple logit model

We first examine two restricted versions of the BLP model: logit and nested logit models

The simple logit model assumes homogeneous preferences: $\alpha_i = \alpha$, $\beta_i = \beta \forall i$

Individuals only differ in their product-specific tastes ε_{ij}

Model rules out systematic individual preferences towards some product characteristics (e.g. preference for small cars rather than large ones)

$$s_{ik} = s_k(\alpha, \beta) = \frac{\exp(\mathbf{x}'_k \boldsymbol{\beta} - \alpha p_k + \xi_k)}{\sum_{j=0}^J \exp(\mathbf{x}'_j \boldsymbol{\beta} - \alpha p_j + \xi_j)}$$

Estimation of the simple logit model

Idea of estimation: match observed market shares s_k^{obs} with those predicted by the model $s_k(\alpha, \beta)$

However: $s_k(\alpha, \beta)$ depend on the vector of unobserved characteristics ξ

Idea: consider ξ to be the error term which distribution is not specified

Estimation using moment conditions (GMM) from orthogonality condition:

$$\mathbb{E}(\xi|\mathbf{Z}) = 0$$

So we need to express ξ as function of observed market shares, parameters and exogenous variables \mathbf{X} : $\xi(\mathbf{s}^{\text{obs}}, \mathbf{X}, \alpha, \beta)$

We need a “market share inversion” procedure

Estimation of the simple logit model

Trick: express the share of the “outside good”, which mean utility δ_0 is normalized to 0

$$s_0(\alpha, \boldsymbol{\beta}) = \frac{1}{\sum_{j=0}^J \exp(\mathbf{x}'_j \boldsymbol{\beta} - \alpha p_j + \xi_j)}$$

Implies:

$$\begin{aligned} \log(s_k) - \log(s_0) &= \delta_k \\ &= \mathbf{x}'_k \boldsymbol{\beta} - \alpha p_k + \xi_k \end{aligned}$$

So we can easily invert the market share equations and get:

$$\xi_k(\alpha, \boldsymbol{\beta}) = \log(s_k) - \log(s_0) - \mathbf{x}'_k \boldsymbol{\beta} + \alpha p_k$$

Estimation of the simple logit model

We have a linear equation to estimate:

$$\underbrace{\log(s_k) - \log(s_0)}_{\text{dependent variable}} = \underbrace{\mathbf{x}_k'}_{\text{exogenous}} \boldsymbol{\beta} - \alpha \underbrace{p_k}_{\text{endogenous}} + \underbrace{\xi_k}_{\text{residual}}$$

GMM is equivalent to an IV regression, we can use 2SLS to estimate $\boldsymbol{\beta}$ and α

We need instruments for price (at least one):

- correlated with price $\mathbb{E}(\mathbf{p}|\mathbf{Z}) \neq 0$
- uncorrelated with ξ_k the demand shock or unobserved product characteristics $\mathbb{E}(\xi|\mathbf{Z}) = 0$

Instruments

Traditional instruments:

- Cost shifters (rk: need cost shifters that vary across products, not very common)
- Functions of other product characteristics, “BLP instruments”:
instrument p_k by $\sum_{j \neq k} x_j^l$
- Intuition = a product's margin and price are constrained by the existence of close substitutes. Function of other products' characteristics as proxy for how crowded is the product space
- Prices in other independent markets, “Hausman instruments” (e.g. different cities)
- Prices in different cities correlated through the costs but independent of the local demand shock
- Instruments invalid if there are common demand shocks that affect prices (e.g. national advertising campaign)

Further discussion on instruments later.

Limitations of the simple logit

Price elasticities (rk: $\alpha > 0$):

$$\begin{aligned}\frac{\partial s_k}{\partial p_k} &= -\alpha \frac{\partial s_k}{\partial \delta_k} = -\alpha s_k(1 - s_k) \\ \frac{\partial s_k}{\partial p_j} &= \alpha s_k s_j\end{aligned}$$

Substitution between two products only depend on market shares

We would prefer substitution to depend on characteristics of products:
more substitution within products with similar characteristics

IIA (independence from irrelevant alternatives): the ratio of market shares of two products does not depend on other products

$$\frac{s_j}{s_k} = \frac{\exp(\mathbf{x}'_j \beta - \alpha p_j + \xi_j)}{\exp(\mathbf{x}'_k \beta - \alpha p_k + \xi_k)}$$

Solutions:

- Nested Logit model
- Random coefficients model

Nested Logit Model

Idea: Group products that are similar and assume a group-specific individual taste shock

Model consistent with a sequential decision: (i) the group (or segment) and (ii) the product inside the group

Example of segmentation:

- City car, sports car, family car...
- Choice between credit card or debit card and then which bank
- Or first the choice of a bank and then the choice of a payment card

Remarks:

- Definition of segments not unique!
- We can try different segmentation to find the most relevant one
- We can have multiple layers of nests
- IIA still holds for products in the same nest but not for products in different nests

Nested Logit Model

Formalization:

$$\varepsilon_{ij} = \zeta_{ig} + (1 - \sigma)\epsilon_{ij}$$

- ϵ_{ij} is iid extreme value, ζ_{ig} distributed such that ε_{ij} is also extreme value
- σ represents the intra-group degree of substitution, it belongs to $[0, 1]$
- If $\sigma \rightarrow 0$: logit case, groups are irrelevant
- If $\sigma \rightarrow 1$: substitution inside groups only

Remark:

- We can use σ to test relevance of the segmentation
 $H_0: \sigma = 0$ vs. $H_a: \sigma \neq 0$
- With multiple levels of nests, we should expect the lower nests to have higher correlations, we can also use this restriction to test the relevance of the ordering of the nests:
 $H_0: \sigma_l \geq \sigma_h$ vs. $H_a: \sigma_l < \sigma_h$

Nested Logit Model

$$U_{ij} = \mathbf{x}_j' \beta - \alpha_i p_j + \xi_j + \zeta_{ig} + (1 - \sigma) \epsilon_{ij}$$

Define \mathcal{J}_g as the set of products in nest g .

Within-nest market shares: ζ_{ig} is irrelevant because it is common to all products in the nest

$$\begin{aligned} s_{j|g} &= P(U_{ij} \geq U_{ik} \quad \forall k \in \mathcal{J}_g) \\ &= P(\delta_j + (1 - \sigma)\epsilon_{ij} \geq \delta_k + (1 - \sigma)\epsilon_{ik} \quad \forall k \in \mathcal{J}_g) \\ &= P\left(\frac{\delta_j}{1 - \sigma} + \epsilon_{ij} \geq \frac{\delta_k}{1 - \sigma} + \epsilon_{ik} \quad \forall k \in \mathcal{J}_g\right) \end{aligned}$$

Same as logit probability, except δ replaced by $\delta/(1 - \sigma)$

$$s_{j|g} = \frac{\exp(\delta_j/(1 - \sigma))}{\sum_{k \in \mathcal{J}_g} \exp(\delta_k/(1 - \sigma))}$$

Nested Logit Model

We define I_g the inclusive value of nest g , i.e. the expected utility of the best product of the nest:

$$I_g = (1 - \sigma) \log \sum_{k \in \mathcal{J}_g} \exp(\delta_k / (1 - \sigma))$$

Probability of choosing a nest \bar{s}_g :

$$\begin{aligned} \bar{s}_g &= \frac{\exp I_g}{\sum_{g'=0}^G \exp I_{g'}} \\ &= \frac{\sum_{k \in \mathcal{J}_g} \exp(\delta_k / (1 - \sigma))^{1-\sigma}}{\sum_{g'=0}^G \left(\sum_{k \in \mathcal{J}_{g'}} \exp(\delta_k / (1 - \sigma)) \right)^{(1-\sigma)}} \end{aligned}$$

So the product market share is:

$$\begin{aligned} s_j &= s_{j|g} \cdot \bar{s}_g \\ &= \frac{\exp(\delta_j / (1 - \sigma))}{\sum_{g'=0}^G \left(\sum_{k \in \mathcal{J}_{g'}} \exp(\delta_k / (1 - \sigma)) \right)^{1-\sigma}} \cdot \frac{1}{\sum_{k \in \mathcal{J}_g} \exp(\delta_k / (1 - \sigma))^\sigma} \end{aligned}$$

Remark: nest 0 contains only the outside good

Nested logit model

Normalization of the outside good mean utility to 0:

$$s_0 = \frac{1}{1 + \sum_{g=1}^G \left(\sum_{k \in \mathcal{J}_g} \exp(\delta_k / (1 - \sigma)) \right)^{1-\sigma}}$$

We use the same trick for the market share inversion, i.e. take the logarithm of s_j/s_0 .

We have:

$$\begin{aligned} \log(s_j/s_0) &= \delta_j/(1 - \sigma) - \sigma \log \sum_{k \in \mathcal{J}_g} \exp(\delta_k/(1 - \sigma)) \\ \text{and } \log s_{j|g} &= \delta_j/(1 - \sigma) - \log \sum_{k \in \mathcal{J}_g} \exp(\delta_k/(1 - \sigma)) \end{aligned}$$

So that:

$$\log s_j - \log s_0 - \sigma \log s_{j|g} = \delta_j$$

Nested logit model

After rearranging we get:

$$\log s_j - \log s_0 = \mathbf{x}'_j \beta - \alpha p_j + \sigma \log s_{j|g} + \xi_j$$

As before, we have a linear equation that we can estimate using 2sls.

We have a new parameter (σ) to estimate and we need to instrument $\log(\bar{s}_{j|g})$

Extension of BLP instruments: sum of product characteristics within nests: instrument $\log(\bar{s}_{j|g})$ by $\sum_{k \neq j, k \in \mathcal{G}_j} X_k$, where \mathcal{G}_j denotes the nest of product j

Substitution patterns under the nested logit

Rk: $\alpha > 0$

$$\begin{aligned}\frac{\partial s_k}{\partial p_k} &= -\frac{\alpha}{1-\sigma} s_k (1 - (1-\sigma)s_k - \sigma s_{k|g}) \\ \frac{\partial s_k}{\partial p_j} &= \frac{\alpha}{1-\sigma} s_k ((1-\sigma)s_j + \sigma s_{j|g}) \quad \text{if } j \text{ and } k \text{ in the same nest} \\ &= \frac{\alpha}{1-\sigma} s_k s_j \quad \text{if } j \text{ and } k \text{ NOT in the same nest}\end{aligned}$$

Random coefficients model

We introduce unobserved individual heterogeneity

$$\begin{aligned} U_{ik} &= \mathbf{x}'_k \boldsymbol{\beta}_i - \alpha_i p_k + \xi_{ik} + \varepsilon_{ik} \\ &= \delta_k + \mu_{ik} + \varepsilon_{ik} \end{aligned}$$

Assume a (multivariate) distribution for the parameters of preferences

$F_{\boldsymbol{\beta}}(\bar{\boldsymbol{\beta}}, \boldsymbol{\Sigma}^x)$ so that: $\beta_i^l = \bar{\beta}^l + \sigma_l v_i^{x,l}$

$$\alpha_i = \bar{\alpha} + \sigma^p v_i^p$$

$$\delta_k = \mathbf{x}'_k \bar{\boldsymbol{\beta}} + \xi_{ik}: \text{“mean utility”}$$

$$\mu_{ik} = \mathbf{x}'_k \boldsymbol{\Sigma}^x \mathbf{v}_i^x - \sigma^p v_i^p p_k: \text{“interaction term”}$$

Two challenges: (i) no closed-form solution for market shares; (ii) more complicated market share inversion

$$s_k(\boldsymbol{\delta}; \boldsymbol{\Sigma}^x) = \int \frac{\exp(\delta_k + \mu_k(\mathbf{v}, \boldsymbol{\Sigma}^x, \sigma^p))}{1 + \sum_{j=1}^J \exp(\delta_j + \mu_j(\mathbf{v}, \boldsymbol{\Sigma}^x, \sigma^p))} dF_{\mathbf{v}}(\mathbf{v})$$

Market share inversion

First challenge: use numerical simulations for an approximation of the integral. We draw vectors of $((\mathbf{v}^{x,l})_{l=1\dots L}, \mathbf{v}^p)$ in the (possibly joint) distribution $F_v(\cdot)$, compute the expression inside the integral for each draw, and take the average.

Second challenge, how to invert market shares to recover $\xi(\Sigma^x, \sigma^p, \bar{\beta}, \bar{\alpha})$?

Preliminary remark: once we have δ , we have ξ with a simple linear transformation:

$$\xi_k = \delta_k - \mathbf{x}'_k \bar{\beta} + p_k \bar{\alpha}$$

Berry (1994) and BLP (1995) prove that the market share system of equations can be inverted to find a unique vector of δ , for a given vector of parameters, i.e. they show that:

$$\delta_k = f^{-1}(\mathbf{s}^{\text{obs}}, \Sigma^x, \sigma^p, \mathbf{x}, \mathbf{p}, F_v)$$

is unique.

Market share inversion

Sketch of the proof that there is a unique $\delta = (\delta_1, \dots, \delta_J)$ such that $\mathbf{s}(\delta_1, \dots, \delta_J) = \mathbf{s}^{\text{obs}}$

This constitutes a system of non-linear equations in δ

A sufficient condition for unicity is that the Jacobian of the matrix that represents the system of equations is diagonal-dominant (see Gale & Nikaidô, 1965)

The Jacobian matrix is:

$$\begin{pmatrix} \frac{\partial s_1}{\partial \delta_1} & \cdots & \frac{\partial s_J}{\partial \delta_1} \\ \vdots & & \vdots \\ \frac{\partial s_1}{\partial \delta_J} & \cdots & \frac{\partial s_J}{\partial \delta_J} \end{pmatrix}$$

Diagonal-dominant means:

$$\left| \frac{\partial s_j}{\partial \delta_j} \right| > \sum_{k \neq j} \left| \frac{\partial s_k}{\partial \delta_j} \right|$$

Market share inversion

Intuition: variation in δ_j must affect more s_j than the shares of all the others products $k \neq j$, which is ensured by the existence of the outside option

Formal proof. We have:

$$\frac{\partial s_j}{\partial \delta_j} + \sum_{k \neq j} \frac{\partial s_k}{\partial \delta_j} + \frac{\partial s_0}{\partial \delta_j} = 0$$

Since $\frac{\partial s_j}{\partial \delta_j} > 0$, $\frac{\partial s_k}{\partial \delta_j}, \frac{\partial s_0}{\partial \delta_j} < 0$, we have: $\partial s_j / \partial \delta_j = |\partial s_j / \partial \delta_j|$ and $-\partial s_k / \partial \delta_j = |\partial s_k / \partial \delta_j|$ for $k \neq j$ or $k = 0$

So we have:

$$\left| \frac{\partial s_j}{\partial \delta_j} \right| = \sum_{k \neq j} \left| \frac{\partial s_k}{\partial \delta_j} \right| + \left| \frac{\partial s_0}{\partial \delta_j} \right|$$

Market share inversion

So

$$\left| \frac{\partial s_j}{\partial \delta_j} \right| > \sum_{k \neq j} \left| \frac{\partial s_k}{\partial \delta_j} \right|$$

which is true as soon as $\left| \frac{\partial s_0}{\partial \delta_j} \right| > 0$, which comes from $s_0 > 0$:

$$\frac{\partial s_0}{\partial \delta_j} = - \int s_j(\mathbf{v}) s_0(\mathbf{v}) dF_{\mathbf{v}}(\mathbf{v})$$

The full proof is in Berry 1994 (Appendix)

We have established uniqueness of δ , now the question is how to find its expression since there is no closed form solution?

Random coefficients model

We have established that if there exists a vector of δ such that $s(\delta, \Sigma^x, \sigma^p, \mathbf{x}, \mathbf{p}, F_{\mathbf{v}}(\mathbf{v})) = s^{obs}$, it is unique.

The question is now how to solve for it?

By iteration, with BLP contraction mapping:

$$\begin{aligned}(\delta_k)^t &= (\delta_k)^{t-1} + \log(s_k^{obs}) - \log(s_k^{theo}(\delta^{t-1}, \Sigma^x, \sigma^p, \mathbf{x}, \mathbf{p}, F_{\mathbf{v}}(\mathbf{v}))) \\(\delta_k)^t &= f_k((\delta)^{t-1})\end{aligned}$$

General conditions for a function f to be contracting:

- (i) $f(\delta) = \delta$
- (ii) $\exists \beta < 1$ s.t. $\forall x, x'$:

$$\|f(x) - f(x')\| \leq \beta \|x - x'\|$$

Intuition: the transformation f ensures that the differences between two different x 's decrease across iterations

Random coefficients model

Sufficient conditions for (ii) to be satisfied are:

$$\begin{aligned}\frac{\partial f_j(\delta)}{\partial \delta_k} &\geq 0 & \forall k \\ \sum_k \frac{\partial f_j(\delta)}{\partial \delta_k} &< 1\end{aligned}$$

Full proof in BLP (1995) - Appendix I

Rk: these are sufficient conditions, they are not necessary

Estimation Method

Based on moment conditions:

- $\mathbb{E} \left[\xi(\Sigma^x, \sigma^p, \bar{\beta}, \bar{\alpha})' \mathbf{z}^m \right] = 0$ for $m = 1, \dots, M$ (no. of instruments)
- Use empirical counterparts of expectations = averages over products and markets
- Compute the empirical counterparts of the moment conditions and use a weighting matrix to obtain the objective function to be minimized

How to recover ξ_k from δ_k ?

- $\xi_k = \delta_k - \mathbf{x}'_k \bar{\beta} + \bar{\alpha} p_k$
- It is also the residual of the IV regression of δ on $[\mathbf{x}, \mathbf{p}]$ (IV because of the price)
- So the linear parameters $\bar{\beta}$ are deterministic functions of the non-linear parameters, so we can “integrate out” the linear parameters from the objective function
- It is very useful since it implies that the dimension of optimization does not increase when we introduce a lot of controls (product characteristics, brand, product, time fixed effects)

Substitution patterns

For $k \neq j$

$$\frac{\partial s_j}{\partial p_k} = \int (\bar{\alpha} + \sigma^p v^p) s_j(\mathbf{v}) s_k(\mathbf{v}) dF_{\mathbf{v}}(\mathbf{v})$$

Assume products j and k have both a high value of characteristic x^l . Individuals with a high v_l have high market shares for both products with high x^l , so large substitution between the two products; while for individuals with low v^l , low substitution

$$\frac{\partial s_j}{\partial p_j} = \int -(\bar{\alpha} + \sigma^p v^p) s_j(\mathbf{v}) (1 - s_j(\mathbf{v})) dF_{\mathbf{v}}(\mathbf{v})$$

rk: $\bar{\alpha} > 0$

Identification

Which variation in the data identifies the parameters of preferences?

Common utility parameters: correlation between choices and product characteristics (across products variation)

Parameters of the unobserved heterogeneity: identification leverages heterogeneity in choices under different choice sets

Thought experiment: two markets (periods), in one market a product is not available, substitution towards other product should be informative about heterogeneity in preferences for a certain characteristics, if market shares change proportionally → homogeneous preferences

Advances on instruments

“Recent” instruments:

- Gandhi & Houde (R&R Econometrica): differentiation instruments
- Unpublished paper but instruments have been used a lot recently
- Idea: what drives demand for product j is not the level of its characteristics x_j^l but its difference with competing products
- Use flexible approximations of an unknown function of the difference (quadratic and spline)
- Quadratic diff IV: $\sum_{j'} (d_{jt,j'}^l)^2, \quad \sum_{j'} (d_{jt,j'}^{\hat{p}})^2$
 - where $d_{j,j'}^l = x_{j'}^l - x_j^l$
 - $d_{j,j'}^{\hat{p}} = \hat{p}_{j'} - \hat{p}_j$
 - \hat{p}_j are the predicted values from a linear regression on instruments (1st stage)
- Local diff IV: $\sum_{j'} |d_{j,j'}^l| \mathbf{1} \left(|d_{j,j'}^l| < \kappa^l \right), \quad \sum_{j'} |d_{j,j'}^{\hat{p}}| \mathbf{1} \left(|d_{j,j'}^{\hat{p}}| < \kappa^{\hat{p}} \right)$
 - κ are a proximity thresholds (e.g. standard-deviations)

Instruments

“Recent” instruments (cont’d):

- Approximation of Chamberlain optimal instruments (Reynaert & Verboven, 2014):
 - Chamberlain (1987) optimal instruments: $\mathbb{E} \left(\frac{\partial \xi_k(\theta)}{\partial \theta} | \mathbf{Z} \right)$
 - Need approximations
 - 1) Approximated by $\mathbb{E} \left(\frac{\partial \xi_k(\hat{\theta})}{\partial \theta} | \mathbf{Z} \right)$, need a first estimate of θ , with standard instruments
 - 2) Evaluate the functions at the expected value of the unobservable $\mathbb{E}(\xi) = 0$ to avoid integrating over the distribution of ξ
- Exogenous policy shocks (e.g. tax change)
- City-time dummies, to take advantage of control and treated groups in the spirit of DiD (see Li, 2017 Restud)

Outline

- 1 Theory and estimation with aggregate data
- 2 Estimation with micro data
- 3 Appendix: GMM estimation

Presentation of the model

Utility of product k :

$$U_{ik} = \mathbf{x}_{ik}'\boldsymbol{\beta} + \varepsilon_{ik}$$

where \mathbf{x}_{ik} is the vector of product characteristics and interactions between individual and product characteristics (e.g size, ingredients, price, interaction between individual income and price...)

$\boldsymbol{\beta}$ represents the valuation of the characteristics, it is the vector of parameters of interest

ε_{ik} is the preference shock, assumed to be iid across products and individuals

cheap but useful remark: we cannot identify the coefficient of a variable that does not vary with the choice (e.g. income alone of the individual)

Estimation of the model

Assume we observe choices of N individuals and their choice set (can be potentially different across individuals)

Denote by $d_{ik} = 1$ if product k is purchased by individual i , $d_{ik} = 0$ if it is not chosen

Estimation by maximum likelihood

$$\max_{\beta} LL = \log \left(\prod_i \prod_j (P_{ij}(\mathbf{x}_i, \beta))^{d_{ij}} \right)$$

which is equivalent to:

$$\min_{\beta} -LL = -\log \left(\prod_i \prod_j (P_{ij}(\mathbf{x}_i, \beta))^{d_{ij}} \right)$$

with:

$$P_{ij} = \frac{\exp(\mathbf{x}'_{ij}\beta)}{\sum_k \exp(\mathbf{x}'_{ik}\beta)}$$

Estimation of the model

Advantages:

- Well-suited for survey data, where we observe rich covariates
- Appropriate when choice characteristics are individual-specific (e.g. duration to work with a transportation mode)
- Likelihood convex, function to maximize well-behaved

Challenges:

- The choice of not purchasing typically not observed
- Solutions
 - model the product choice conditional on buying
 - make an assumption on the number (and possibly the characteristics) of consumers who did not buy any product (= define potential market and its characteristics)
- Consistency requires exogeneity of x , not true for the price
- Unobserved product characteristics? Can be captured with product dummies, but this increases the parameter space

Estimation of the model

What can we put in \mathbf{x}_{ij} ?

Depends of the data:

- Repeated purchases (panel of individual choices in different environments): we can have product \times individual fixed effects: ξ_{ij}
- Cross-section of individual choices: we need to specify the individual heterogeneity through interactions between individual characteristics and product characteristics

$$D_i \times \mathbf{x}_j$$

with D_i some observable individual characteristics (age, income...)
 \mathbf{x}_j product characteristics

Random coefficients

We can also introduce **unobserved heterogeneity** through random coefficients like in BLP

We specify the distribution of a parameter of preference β and estimate its parameters (mean and standard deviation): $\beta_i \sim F_\beta(\bar{\beta}, \Sigma^\beta)$ with $\bar{\beta}, \Sigma^\beta$ to be estimated

This is called a mixed-logit model

Estimation: Simulated Maximum Likelihood (because we compute likelihood using numerical simulations)

Endogeneity

Introduce unobserved characteristics ξ_k :

$$\begin{aligned} U_{ik} &= \mathbf{x}'_{ik}\boldsymbol{\beta} + \xi_k + \varepsilon_{ik} \\ &= \delta_k + \mu_{ik} + \varepsilon_{ik} \end{aligned}$$

Unobserved characteristics likely to be correlated to some \mathbf{x} , e.g. the **price**

- Endogeneity since $E(\xi|\mathbf{p}) \neq 0$
- Conditional on \mathbf{p} , residual is no longer centered (e.g. we expect higher residuals for higher prices)

We can still use max-likelihood method but proceed as follows:

- First estimate δ with product fixed-effects using maximum likelihood
- Regress δ on $[\mathbf{x}, \mathbf{p}]$ using an IV approach to get $\hat{\boldsymbol{\beta}}$
- Drawback: parameter space may become large!

Endogeneity

Alternative: use control function approach

Idea: regress endogenous variable(s) on instruments, and use the residuals of the regression as an extra explanatory variable: the **control function**

Intuition: Controlling for the residual of a first-stage equation, error term is uncorrelated with the endogenous variable

Issues: (i) method relies on the correct specification of the control function
(ii) relies on an assumption of the distribution of errors in the regression and joint distribution of errors of the model and regression

Reference: Petrin & Train (2009)

Control function approach

Formalization in the case of a linear regression:

$$y_j = \mathbf{x}_j' \boldsymbol{\beta} + \alpha p_j + u_j$$

and some instruments \mathbf{z} such that $\mathbb{E}(\mathbf{z}'\mathbf{u}) = 0$. Define the linear control function:

$$p_j = \mathbf{z}_j' \boldsymbol{\pi} + v_j$$

Then, compute the linear projection of \mathbf{u} on \mathbf{v} : $u_j = \rho v_j + e_j$

By construction $\mathbb{E}(\mathbf{v}'\mathbf{e}) = 0$ and $\mathbb{E}(\mathbf{z}'\mathbf{e}) = 0 \Rightarrow \mathbf{e}$ “better” error term

So we replace u by its expression in \mathbf{e} in the initial equation:

$$y_j = \mathbf{x}_j' \boldsymbol{\beta} + \alpha p_j + \rho v_j + e_j$$

Of course, \mathbf{v}_j is not observed so we replace it by its estimate from the first step equation $\hat{\mathbf{v}}$ estimated using OLS

Note: since we rely on an estimate, need to take the first-stage error in the calculation of standard errors (bootstrap, Newey-McFadden's two-step formula)

Control function approach in the logit model

1st special case:

$$U_{ij} = \mathbf{x}'_{ij}\boldsymbol{\beta} + \alpha p_{ij} + \varepsilon_{ij}$$

with $\mathbb{E}(\varepsilon|\mathbf{p}) \neq 0$

Assume we have \mathbf{z}_{ij} such that:

$$p_{ij} = f(\mathbf{z}_{ij}, \gamma) + \mu_{ij}$$

with $\mathbb{E}(\varepsilon, \boldsymbol{\mu}|\mathbf{z}) = 0$ but $\mathbb{E}(\varepsilon|\boldsymbol{\mu}) \neq 0$

So we replace ε_{ij} by its conditional expectation:

$$\varepsilon_{ij} = \mathbb{E}(\varepsilon_{ij}|\mu_{ij}) + \tilde{\varepsilon}_{ij}$$

with $\mathbb{E}(\tilde{\varepsilon}_{ij}|\mu_{ij}) = 0$

Simplest assumption: $\mathbb{E}(\varepsilon_{ij}|\mu_{ij}) = \lambda\mu_{ij}$, so the utility function becomes

$$U_{ij} = \mathbf{x}'_{ij}\boldsymbol{\beta} + \alpha p_{ij} + \lambda\mu_{ij} + \tilde{\varepsilon}_{ij}$$

Distribution of $\tilde{\varepsilon}$? If we assume $(\mu_{ij}, \varepsilon_{ij}) \sim N(0, \Sigma)$ then $\tilde{\varepsilon}_{ij} \sim N(\cdot)$, so we have a probit (or mixed probit) model

Control function approach

2nd special case:

$$U_{ij} = \mathbf{x}'_{ij}\boldsymbol{\beta} + \alpha p_{ij} + \varepsilon_{ij}^1 + \varepsilon_{ij}^2$$

with $\mathbb{E}(\varepsilon_{ij}^1 | p_{ij}) \neq 0$, $\mathbb{E}(\varepsilon_{ij}^2 | p_{ij}) = 0$

Assume we have \mathbf{z}_{ij} such that:

$$p_{ij} = f(\mathbf{z}_{ij}, \gamma) + \mu_{ij}$$

with $\mathbb{E}(\varepsilon_{ij}^1, \mu_{ij} | \mathbf{z}_{ij}) = 0$ but $\mathbb{E}(\varepsilon_{ij}^1 | \mu_{ij}) \neq 0$

So we replace ε_{ij}^1 by its conditional expectation:

$$\varepsilon_{ij}^1 = \mathbb{E}(\varepsilon_{ij}^1 | \mu_{ij}) + \tilde{\varepsilon}_{ij}^1$$

with $\mathbb{E}(\tilde{\varepsilon}_{ij}^1 | \mu_{ij}) = 0$ and $\mathbb{E}(\varepsilon_{ij}^1 | \mu_{ij}) = \lambda \mu_{ij}$, so the utility function becomes

$$U_{ij} = \mathbf{x}'_{ij}\boldsymbol{\beta} + \alpha p_{ij} + \lambda \mu_{ij} + \tilde{\varepsilon}_{ij}^1 + \varepsilon_{ij}^2$$

If we assume $(\mu_{ij}, \varepsilon_{ij}^1) \sim N(0, \Sigma)$ then $\tilde{\varepsilon}_{ij}^1 \sim N(0, \sigma^{\tilde{\varepsilon}})$, and because $\tilde{\varepsilon}_{ij}^1 \perp \varepsilon_{ij}^2$ we can use the logit formula but need to integrate numerically over $\tilde{\varepsilon}_{ij}^1$

Estimation with a combination of data

Motivation: sometimes we have aggregate level data + some individual data

- Sample of individual choices (e.g. surveys)
- Local sales
- Additional data link choices to individual characteristics
- Crucial to identify Σ^D when heterogeneity in preferences has a parametric form:

$$\beta_i = \bar{\beta} + D_i' \Sigma^D + v_i' \Sigma^v$$

Problem: individual data cannot be directly used

- Not exhaustive
- Not precise (recall that observed purchases are realizations of product market share, if s_j is small, need a large sample)

Solution: form “micro”-moment conditions, MicroBLP (2004), Petrin (2002), Nurski & Verboven (2016)

Estimation with a combination of data

Idea: match theoretical covariances to observed ones through moment conditions

Micro-moments can take various forms:

- Covariance between demographic characteristics and purchase characteristic (e.g. covariance between car price and income)
- Covariance between characteristics of first and second choices (microBLP, 2004)
- Covariance between characteristics of purchases and demographic characteristics at the municipality level (Nurski & Verboven, 2016)

Estimation with a combination of data

Example: moments from covariance between purchase characteristics and demographic characteristics at the local level

Example: covariance between median income i_m in municipality m and average car price if municipality m

$$g(\theta) = \sum_{m=1}^M \left[\phi_m (i_m - \bar{i}) \cdot (p_m - \bar{p}) \right] - \text{cov theo.}$$

p_m is the average price in municipality m : $p_m = \sum_j s_{mj} p_j$ and $\bar{p} = \sum_j s_j p_j$

$$g(\theta) = \frac{1}{J} \sum_{j=1}^J \left[\sum_m \phi_m s_{mj} (i_m - \bar{i}) \cdot (p_j - \bar{p}) - \sum_m \phi_m s_{mj}(\theta) (i_m - \bar{i}(\theta)) \cdot (p_j - \bar{p}(\theta)) \right]$$

Since we exactly match the aggregate market shares, $\sum_m \phi_m s_{mj}(\theta) = s_j$, $\bar{p}(\theta) = \bar{p}$, and the moments can be written as:

$$g(\theta) = \frac{1}{J} \sum_{j=1}^J \frac{\sum_m \phi_m [s_{mj}(i_m - \bar{i}) - s_{mj}(\theta)(i_m - \bar{i}(\theta))]}{s_j} \cdot (p_j - \bar{p})$$

Outline

- 1 Theory and estimation with aggregate data
- 2 Estimation with micro data
- 3 Appendix: GMM estimation

GMM estimation method

We use moment conditions to estimate parameters of the model

Moment conditions are of the form $\mathbb{E}(\mathbf{z}'u(\boldsymbol{\theta})) = 0$

Where $u(\boldsymbol{\theta})$ is the residual of the model and $\boldsymbol{\theta}$ the vector of parameters to estimate

\mathbf{z} are exogenous variables + instruments

We use the empirical counterpart of the moment condition

$$\frac{1}{N} \sum_{i=1}^N \mathbf{z}'_i \cdot u_i(\boldsymbol{\theta})$$

Model estimated by minimizing the moment condition in a norm:

$$\hat{\boldsymbol{\theta}} = \arg \min \left(\frac{1}{N} \sum_{i=1}^N (\mathbf{z}'_i \cdot u_i(\boldsymbol{\theta})) \right)' \mathbf{W} \left(\frac{1}{N} \sum_{i=1}^N (\mathbf{z}'_i \cdot u_i(\boldsymbol{\theta})) \right)$$

Application to the cement model

Recall the model of market equilibrium for the cement market

- Demand (inverse price function):

$$P_t = a_0 + a_1 POP_t + a_2 I_t - b_0 Q_t + e_t^D$$

- Supply (marginal cost function):

$$\left(P_t - b_0 \frac{Q_t}{N_t} \right) = m_0 + m_1 W_t + m_2 M_t + m_3 \frac{Q_t}{K_t} + e_t^{MC}$$

- We can estimate the demand and supply models jointly using GMM
 - Using demand moments:

$$\mathbb{E}(\mathbf{Z}_D' \mathbf{e}^D) = 0$$

where $\mathbf{Z}_D = \{Intercept, POP, I, W, M, K\}$

- Using supply moments:

$$\mathbb{E}(\mathbf{Z}_S' \mathbf{e}^S) = 0$$

where $\mathbf{Z}_S = \{Intercept, POP, I, W, M, K\}$

Exercise

Estimate demand and supply parameters using moment conditions

Here: $\mathbf{Z}_D = \mathbf{Z}_S = \mathbf{Z}$, define $\tilde{\mathbf{W}} = (\mathbf{Z}'\mathbf{Z})^{-1}$, the weighting matrix can be:

$$\mathbf{W} = \begin{pmatrix} \tilde{\mathbf{W}} & 0 \\ 0 & \tilde{\mathbf{W}} \end{pmatrix}$$

Hints:

- Use `fminunc` (gradient-based) or `fminsearch` (simplex)
- Check the GMM function, if no error, $\mathbf{e}^D = \mathbf{e}^S = 0$, GMM objective = 0
- Set the appropriate tolerance levels (`TolX`, `TolFun`,...)

To go further:

- Estimate the model using the 2 step GMM to estimate the optimal weighting matrix and check the gain in precision using monte carlo simulations
- “Integrate out” some parameters to restrict the non-linear search to b_0 only
